The seminal Batchelor-Green’s (BG) theory on the hydrodynamic interaction of two spherical particles of radii \( a \) suspended in a viscous shear flow assumes unbounded fluid. In the present paper we study how a rigid plane wall modifies this interaction. Using an integral equation for the surface traction we derive the expression for the particles’ relative velocity as a sum of the BG’s velocity and the term due to the presence of a wall at finite distance, \( z_0 \). Our calculation is not the perturbation theory of the BG solution, so the contribution due to the wall is not necessarily small. We indeed demonstrate that the presence of the wall is a singular perturbation, i.e., its effect cannot be neglected even at large distances. The distance at which the wall significantly alters the particles interaction scales as \( z_0^{3/5} \). The phase portrait of the particles’ relative motion is different from the BG theory, where there are two singly connected regions of open and closed trajectories both of infinite volume. For finite \( z_0 \), besides the BG’s domains of open and closed trajectories, there is a domain of closed (dancing) and open (swapping) trajectories that do not materialize in an unbounded shear flow. The width of this region grows as \( 1/z_0 \) at smaller separations from the wall. Along the swapping trajectories, which have been previously observed numerically, the incoming particle is turning back after the encounter with the reference particle, rather than passing it by, as the BG theory anticipates. The region of dancing trajectories has infinite volume and is separated from a BG-type domain of closed trajectories that becomes compact due to presence of the wall. We found a one-parameter family of equilibrium states that were previously overlooked, whereas the pair of spheres flows as a whole without changing its configuration. These states are marginally stable and their perturbation yields a two-parameter family of the dancing trajectories, whereas the test particle is orbiting around a fixed point in a frame comoving with the reference particle. We suggest that the phase portrait obtained at \( z_0 \gg a \) is topologically stable and can be extended down to rather small \( z_0 \) of several particle diameters. We confirm this hypothesis by direct numerical simulations of the Navier-Stokes equations with \( z_0 = 5a \). Qualitatively the distant wall is the third body that changes the global topology of the phase portrait of two-particle interaction.

I. INTRODUCTION

Small particles, droplets, and bubbles are ubiquitously present in flowing fluids. When a suspended particle is transported by a viscous fluid, it modifies the flow around it. If another particle happens to be in the region of the modified flow, then mutual hydrodynamic interactions between the particles will take place. The interactions are given implicitly by imposing boundary conditions on the flow that must hold simultaneously on the surfaces of all interacting particles [1,2]. This setting is inconvenient for analyses, both theoretical and numerical. Thus, there is no answer to even the simplest questions, for instance, whether there can be a nontrivial stationary configuration of particles that would flow as a whole due to the hydrodynamic interaction. Although these interactions somewhat resemble electrostatic interactions, there is no a hydrodynamic counterpart of Earnshaw’s theorem [3] stating that such simple configurations are impossible. Here we provide an example of this possibility in the presence of a boundary and demonstrate that boundaries can have surprising and nontrivial effects on hydrodynamic interactions.

The only well-studied case of hydrodynamic interactions of particles transported by nonuniform flow is the case of two particles in a time-independent low Reynolds number linear flow. This was studied in the seminal Batchelor and Green’s paper [4], see also Ref. [5] for more details and an account of various contributions to the problem. If the particles’ (and fluid) inertia can be entirely neglected, then the vector between the particle centers obeys an autonomous first-order evolution equation, which gives its rate of change as a function of the instantaneous value. The use of the symmetries makes it possible to quantify the interaction by the two scalar functions of the distance, which have been tabulated [4]; see also Ref. [2]. This case presents no stationary configurations for the two particles. One of the main applications is the Poiseuille flow in the channel shown in Fig. 1.

If both particles are far from the walls, \( z_0 \gg a, r \), then they can seemingly be considered as flowing in an unbounded shear flow and the analysis of Refs. [4–6] applies. The BG theory thus predicts that there are no possible stationary configurations of the particle pair. Here we demonstrate that the approximation of an unbounded flow overlooks such configurations and also other phenomena,
which hold independently of how large $z_0$ is, cf. Ref. [7]. Thus, the presence of the wall exhibits a singular perturbation of the BG theory.

Recently, stationary configurations of particles transported in microfluidic channels attracted attention due to the possibility of flow-assisted microfabrication by using a combination of hydrodynamic and nonhydrodynamic (i.e., adhesive) interactions [8,9]. Under certain conditions, the particles can self-assemble into clusters of different morphology that flow with no change of interparticle distances; see Ref. [10] for detailed discussions. These micron-scale clusters can then be solidified and collected from the flow, and be potentially used for fabrication of functional metamaterials. To theoretically explain and subsequently predict the structure formation of the suspended particles observed in experiments, Shen et al. [9] proposed a model based on a dipolar asymptotic form of hydrodynamic interaction. Notice that the dipolar form only holds at large particle separations (it was derived in detail using the fundamental solution for the channel flow [11]; see Ref. [12] and also references therein). One reason for the apparent applicability of this description, despite the particles were close to each other, is likely the dominance of the adhesive radial forces between particles at close proximity, such that any hydrodynamic interaction producing a nonzero tangential velocity component would yield a similar cluster formation dynamics (see Ref. [10] for further evidence). In contrast, a consistent predictive theory of hydrodynamic interactions should hold irrespective of the presence of adhesive forces, and allow for analysis of interaction of flowing particles at close proximity and near the wall, as in experimental setup [9]. The present paper is a step toward this theory.

There are two differences between the channel flow and the unbounded shear flow considered in the BG theory [4,6]. The velocity profile of the channel flow is quadratic [13] in the coordinate rather than linear. This difference is often irrelevant when the interacting particles are located much closer to one of the channel walls, so that the flow can be closely approximated by the linear shear flow. This is the case we consider in the present paper. Another difference, is that the no-slip rigid wall is always at a finite distance and it interacts with the flowing particles.

We first consider the evolution of the interparticle distance when the effect of the wall is neglected and the BG theory applies. It is useful to consider the three-dimensional phase space spanned by all possible distances $r$ between the spheres’ centers where one of them is at the origin. The distance $r(t)$ between the spheres’ centers obeys an autonomous evolution equation which means that there is a well-defined phase space flow $V^0(r)$ such that $\dot{r} = V^0[r(t)]$ and a unique trajectory passes through each point. This is the consequence of neglecting particles’ and fluid inertia and the translational invariance due to which the shear resistance matrix depends on $r$ only, cf. [14] (translation in a linear flow changes the flow by a constant vector, irrelevant by Galilean invariance). The flow $V^0(r)$ does not vanish anywhere so that there are no steady configurations. The absence of critical points with $V^0(r) = 0$ implies a simple structure of the phase space. This can be most readily observed in the symmetry plane formed by the horizontal flow direction $x$ and the vertical velocity gradient direction $z$ (see Fig. 2). The trajectories that belong to the plane never leave it, $V_x(y = 0) = 0$, and can be considered separately. There is a simple dichotomy of the trajectories: closed trajectories crossing the $x$ axis and open trajectories that do not cross the $x$ axis. The open trajectories describe the faster particle overtaking the slower one. The particles return to their original vertical positions following the hydrodynamic encounter and there is fore-and-aft symmetry of the phase portrait. In contrast, the trajectories that cross the $x$ axis are closed, corresponding to a bound pair of spheres orbiting around each other. Open and closed trajectories are separated by the separatrix that touches the $x$ axis asymptotically at large distances [6]. Rotation of this separatrix around the $z$ axis creates an axisymmetric surface that separates the regions of open and closed trajectories in space (it is not readily evident how this axial symmetry could be guessed a priori without writing down the equations). The region of closed trajectories has an infinite volume, which presents difficulties in, e.g., calculation of the effective viscosity of a dilute hard-sphere suspension at the quadratic order in concentration [15].

We demonstrate here that when a distant wall is considered, the evolution of $r$ remains autonomous in the leading approximation, $\dot{r} = V[r(t)]$. Thus, at any finite $z_0 \gg a$ we can still
FIG. 2. Phase portrait of the trajectories in the symmetry $xz$ plane, within the BG approximation of $z_0 = \infty$. All lengths are scaled with the particle radius $a$. Throughout the paper the reference sphere is at the origin and the trajectories of the second sphere are shown. Due to the fore-and-aft and top-down symmetries only one quadrant is depicted. The two types of the trajectories—closed (blue) and open (red), are separated by the separatrix, the open trajectory that asymptotically approaches the $x$ axis [4,6]. For two spheres at the same vertical line, the maximal separation for closed trajectories is of order of $10^{-5}$; see Ref. [5]. As a result, at this resolution, the trajectories are indistinguishable when approaching the $z$ axis. This includes the shown open trajectory that crosses the $z$ axis slightly above the closed trajectories. The time-period of revolution along the shown closed trajectory is more than 700 (here and thereafter the time units of inverse shear rate $\dot{\gamma}^{-1}$ are used).

examine the phase portrait, which is, however, qualitatively different from that in Fig. 2. Our calculation is not a perturbation theory of the BG solution as we do not assume $V \approx V^0$, so the disturbed phase space flow $V(r)$ is significantly different from $V^0$. The change in topology occurs because at finite $z_0$ there exist critical points at which $V(r)$ vanishes; see the phase portrait in the symmetry plane in Fig. 3. The saddle (hyperbolic) point $r_s$, the closer of the two critical points to the origin, is unstable. The other neutral equilibrium (elliptic) point $r_c$ corresponds to a marginally stable configuration, where the pair flows without changing its interparticle distance and orientation; see Fig. 4(a). Not too large deviations from this state result in the sphere orbiting around this elliptic point. These dancing trajectories would have rather unusual appearance when considered in the laboratory frame: While one sphere travels downstream, the other sphere revolves around a point comoving in space with the first sphere; see Fig. 4(b). The phase plane at $x > 0$ is characterized by two disconnected regions of closed trajectories shown in Fig. 3 by the blue curves. The region to the left of the separatrix (blue) that crosses $x = r_s$ resembles the BG’s closed trajectories. The trajectories around the elliptic point $(r_c, 0)$ are solely due to the presence of the wall. The lowest red curve is an open trajectory similar to the BG’s: After the encounter the vertical separation is restored to its initial value. In contrast to that, along the (red) trajectories circumventing the elliptic point, the vertical separation of the particles reverses sign after the encounter. We call these “swapping trajectories,” since they seem to correspond to the numerical findings of Ref. [7] at $z_0 \sim a$, where trajectories with particles swapping their vertical positions after the encounter in a channel flow were reported (careful consideration of the figure presented in Ref. [7] reveals slight changes of the vertical coordinates which seem to be a higher order effect than that considered here). The phase portrait for the evolution of interparticle distance along the swapping trajectory obtained in Ref. [7] numerically, agrees with that predicted here theoretically. To prove that the sign-reversal of the vertical separation predicted here implies swapping, it has to be shown that the center of mass
FIG. 3. The phase portrait in the symmetry $xz$ plane at finite $z_0 = 5$. The fore-and-aft and top-down symmetries survive the wall perturbation in the leading order. The phase portrait exhibits two critical (equilibrium) points: the saddle (hyperbolic) point $r_s$ and the neutral equilibrium (elliptic) point $r_c$, representing a completely different topology from the BG theory in Fig. 2. As $z_0 \rightarrow \infty$, the topology of the phase portrait is preserved, while the critical points are being shifted to infinity.

of the pair is not displaced vertically as a result of the encounter. We leave the rigorous proof for future work, focusing here on the evolution of interparticle distance only. Thus, the use of the term “swapping trajectories” here, strictly speaking, refers to open trajectories with sign-reversal of the vertical separation following the encounter.

The three-dimensional trajectories are more complex. The circle of radius $r_c$ around the $z$ axis provides the critical curve with $V(r) = 0$. The configurations with $r$ on that circle are stationary, so that for instance there is a stationary pair where only the $y$ coordinates of the particles are different. Displacements from these stationary configurations result in closed trajectories that loop around the critical circle; see Fig. 5. In contrast with the symmetry plane, where the BG trajectories display no

FIG. 4. (a) There is a unique value of the streamwise separation distance between two particles, $x = r_c$, flowing along the same streamline of the Poiseuille flow, for which they flow steadily without changing their configuration. The stability of such motion is marginal, cf. panel (b). The value $r_c = 4z_0$ is confirmed in the numerical simulations of the Navier-Stokes equations for $z_0 = 5$. (b) Trajectories that pass through points around the stationary point $x = r_c$, $z = 0$, crossing $x$ axis at distance larger than $2\sqrt{2}z_0$, exhibit a peculiar dancing dynamics. In the coordinate frame comoving with the trailing (left) particle, the leading (right) sphere follows an elongated closed orbit around $(r_c, 0)$. Similar trajectories hold outside the symmetry plane.
FIG. 5. The blue line depicts the closed trajectory that forms a loop around the critical circle of radius $r_c$ (whose segment is shown by the green line) for $z_0 = 5$. The trajectory can be shrunk to a (necessarily critical) point by continuously changing the initial conditions. The red line shows the BG trajectory that starts from the same initial condition as the blue line. The period of revolution along the closed trajectory is 1165.

behavior similar to dancing, some of the three-dimensional BG trajectories do look rather similar (notice that it was not stressed in the original work or in Ref. [5]); see Fig. 6 for comparison.

We emphasize the topological difference between the phase portrait in Fig. 3 and that of the BG theory in Fig. 2. There are two disconnected regions of closed trajectories. In one region the particles orbit each other, similar to the $z_0 = \infty$ approximation, however, the volume of this region is finite. The other region contains dancing closed trajectories and at large $x^2 + y^2$ it is bounded by the surface of revolution $|z| \propto z_0 (x^2 + y^2)^{-3/2}$. This is similar to the BG bounding surface, $|z| \propto (x^2 + y^2)^{-3/2}$, however, boosted by the large $z_0$ factor. In both cases the volume of the phase space domain containing closed trajectories diverges, so the divergences in the second order in particle concentration stress calculations of Ref. [15] are not regularized by the wall. At finite $z_0$ the two regions of closed trajectories are separated by a region of a new type of open swapping trajectories that, in contrast to the BG theory, cross the $x$ axis. Then the top-down symmetry, which holds remarkably in the presence of the wall, implies that for open trajectories that cross the $x$ axis, the vertical component of the interparticle distance reverses its sign, as in numerically observed swapping trajectories [7]. At least some features of the presented topology, derived theoretically at $z_0 \gg a$, work accurately down to $z_0 = 5a$, as demonstrated by our in-house numerical simulations of the Navier-Stokes equations.

In Sec. II we present the detailed derivation of the evolution equation for the interparticle distance in the wall-bounded shear flow. Section III demonstrates why the wall presents a singular perturbation of the BG theory. In Sec. IV we review the BG trajectories that serve as the reference point of our study. We present the results of the numerical solutions of the derived evolution equation in Sec. V. Section VI presents full solution of equation of motion in the dancing-swapping region. Section VII presents the confirmation of the theory by direct numerical simulations of the motion of a pair of spheres in the Poiseuille flow. In Sec. VIII we conclude our results, discuss the applicability of the BG theory, and formulate some open questions.
II. EVOLUTION OF THE DISTANCE BETWEEN TWO PARTICLES TRANSPORTED BY A SHEAR FLOW NEAR WALL

In this section we derive the autonomous evolution equation for the distance \( r(t) \) between two spheres transported by the Poiseuille flow. We make the simplifying assumption that both spheres are much closer to one of the bounding walls than the other. Thus, the particles are effectively transported by the shear flow and not the parabolic velocity profile. The hydrodynamic interaction of particles transported by an unbounded shear flow are well-studied and their velocities \( V^0_\alpha, \alpha = 1, 2 \) were considered in Ref. [4]. This analysis serves as a starting point of our study. We also assume that the distance to the wall is much larger than the particles’ radii. We derive the particles’ relative velocity as a sum of \( V^0_\alpha \) and the correction velocity \( \delta V_\alpha \). The correction velocity is not necessarily smaller than \( V^0 \), as our solution is not a perturbation around the solution for an unbounded shear flow.

A. Direct approach

We set the problem and consider its formulation using the flow for infinitely separated walls as a reference. The problem of two spheres driven by the Poiseuille flow is described by

\[
\begin{align*}
\nabla p &= \eta \nabla^2 u, \quad \nabla \cdot u = 0, \quad u(z = 0) = u(z = h) = 0, \\
\n\n\left[ u_x(\infty) = \frac{z(z - h)\nabla_x p^0}{2\eta}, \quad u(S_\alpha) = V_\alpha + \Omega_\alpha \times (x - x_\alpha), \right.
\end{align*}
\]

where \( \alpha = 1, 2 \) are the indices of the spheres, \( x_\alpha \) are the coordinates of the centers, and \( S_\alpha \) is the surface of the \( \alpha \)th sphere. We designate the flow by \( u \), and the translational and rotational velocities of the spheres by \( V_\alpha \) and \( \Omega_\alpha \). The constant pressure gradient \( \nabla p^0 = -|\nabla_x p^0|\hat{x} \) drives the flow in
We assume that the spheres have equal radii, \( a \), although most of the calculations below can be done without this assumption. We will use below \( a \) as the unit of length so that the radii are 1. We assume that the particle inertia is negligible so that the values of \( V_\alpha \) and \( \Omega_\alpha \) are determined from the conditions that the total force and torque from the fluid on either particle is zero,

\[
\int_{S_\alpha} t \, dS = 0, \quad \int_{S_\alpha} (x - x_\alpha) \times t \, dS = 0, \tag{2}
\]

where we have introduced the surface traction \( t \), which can be written via the stress tensor \( \sigma_{ij} \) as

\[
t_i(x) = \frac{\sigma_{ik}(x - x_\alpha)_k}{a}, \quad \sigma_{ik} = -p \delta_{ik} + \eta (\nabla_i u_k + \nabla_k u_i),
\]

where \( x \) belongs to \( S_\alpha \). We observe that if the spheres are much closer to the wall at \( z = 0 \) than at \( z = h \), then we can use different boundary conditions in Eq. (1),

\[
u(z = 0) = 0, \quad \nu(\infty) = \hat{\gamma} z \hat{x}, \quad \hat{\gamma} = \frac{h |\nabla_x p^0|}{2\eta}, \tag{4}
\]

where we introduced the effective shear rate \( \hat{\gamma} \) in terms of the parameters defining the Poiseuille flow. The boundary conditions at \( S_\alpha \) are unaltered. Without the boundary condition at \( z = 0 \) we reduce to the problem of motion of two spheres in an unbounded shear flow considered in Ref. [4]. We designate all quantities of this problem by the superscript zero. Thus, \( \nu^0 \) is the unbounded shear flow for the two spheres with translational and rotational velocities \( V_\alpha^0 \) and \( \Omega_\alpha^0 \), which obey Eq. (2) with \( t = t^0 \). We look for the solution as superposition of \( \nu^0 \) and the flow perturbation \( \delta \nu \) (where the use of \( \delta \) does not imply smallness of \( \delta \nu \)). We thus have

\[
\nabla \delta p = \eta \nabla^2 \delta \nu, \quad \nabla \cdot \delta \nu = 0, \quad \delta \nu(z = 0) = -\nu^0(z = 0), \quad \delta \nu(\infty) = 0,
\]

\[
\delta \nu(S_\alpha) = \delta V_\alpha + \delta \Omega_\alpha \times (x - x_\alpha),
\]

where we introduced deviations of the velocities and of the surface traction from their values in an infinite domain,

\[
\delta V_\alpha = V_\alpha - V_\alpha^0, \quad \delta \Omega_\alpha = \Omega_\alpha - \Omega_\alpha^0, \quad \delta t = t - t^0.
\]

The deviations of the velocities are fixed by the condition that the deviation from the surface traction obeys Eqs. (2) with \( \delta t \) instead of \( t \). We notice that the flow \( \nu^0(z = 0) \) in Eq. (53) is induced by the spheres, since the unperturbed flow vanishes at \( z = 0 \). Thus, \( \nu^0(z = 0) \) vanishes at infinity as necessary for consistency of the boundary conditions at the plane and at infinity. For the distant wall the flow \( \nu^0(z = 0) \) can be simplified. This flow obeys the integral representation (see the derivation in Appendix A),

\[
u^0_i(x) = \hat{\gamma} \delta_{il} z - \sum_\alpha \int_{S_\alpha} Y_{il}(x - x') \nu^0_\alpha(x') \, dS \frac{1}{8\pi \eta} \delta_{il} \frac{r_i r_l}{r^3}, \quad r = x - x',
\]

where \( Y_{il} \) is the Oseen tensor or the Green’s function of the Stokes flow in an unbounded fluid [2]. If the vertical positions \( z_\alpha \) of the centers of both spheres are much larger than their radii, \( a \), then the asymptotic expansion of \( \nu^0_i(z = 0) \) in \( a/z_\alpha \) is obtained by Taylor expansion of \( Y_{il}(x - x') \) in Eq. (7) near \( x' = x_\alpha \). Using the condition of zero force we find that, at the leading order,

\[
\nu^0_i(z = 0) \approx \frac{1}{8\pi \eta} \frac{\partial}{\partial x_m} \left[ \sum_\alpha Y_{il}(x - x_\alpha) S^\alpha_{lm}\big|_{z = 0} \right] + \frac{\delta_{lm}(x - x_\alpha) p^0_\alpha(x)}{3} \int_{S_\alpha} (x - x_\alpha)_m t^0_\alpha(x) \, dS, \tag{8}
\]

where the traceless tensor \( S^\alpha_{lm} \) is [4] the force dipole strength of sphere \( \alpha \). The \( \delta_{lm} \) term can be added since \( \nabla_i Y_{il} = 0 \). The force dipole strengths obey a general form derived in Ref. [4]. We have
where the scalar functions \( K, L, \) and \( M \) depend on the interparticle distance \( r/a \) only (we omitted the prime in the notation of Ref. [4], as the spheres have identical radii in our case). These functions can be completely found only numerically and are considered below as given. We can use Eq. (8) instead of the boundary condition at \( z = 0 \) in Eq. (53). The first reflection [1] gives the leading order approximation for \( \delta V_\alpha \) as in the Lorentz solution for a sphere in the presence of a distant wall [1]. The compact expansion can be found below from integral representations.

**B. Integral equation for velocities**

Here we derive the integral equation that determines the particle velocities. For future generalization to the case where the distances from the spheres to both walls are comparable we perform the derivation starting from the full formulation given by Eq. (1). We use the integral representation of the flow [12,16,17],

\[
S_{lm}^1 = S_{lm}^2 = S_{lm}
\]

with

\[
\frac{3S_{lm}(r)}{10 \pi \eta a^3 \gamma} = (\delta_{l\alpha}\delta_{mz} + \delta_{m\alpha}\delta_{lz})(1 + K) + \left[ \frac{r_l(x \delta_{mz} + z \delta_{mx}) + r_m(x \delta_{lz} + z \delta_{lx})}{r^2} - \frac{4xz \delta_{lm}}{3r^2} \right] L
\]

\[
+ \frac{2xz}{r^2} \left( \frac{r r_m}{r^2} - \delta_{lm} \right) M,
\]

(9)

where \( \delta \) is defined by

\[
\delta_{l\alpha}\delta_{mz} + \delta_{m\alpha}\delta_{lz} = \delta_{\alpha l}\delta_{mz} + \delta_{m\alpha}\delta_{lz} = \delta_{m\alpha}\delta_{lz} = \delta_{\alpha m}\delta_{lz}.
\]

and it was derived in Ref. [11]. We study the velocities \( V_\alpha \) by using the integral equation for the surface traction \( t(x) \). This equation is obtained by taking \( x \) in Eq. (10) to the surface of the spheres which gives

\[
(V_\alpha)_l + [\Omega_\alpha \times (x - x_\alpha)]_l = (2\eta)^{-1} \delta_{l\alpha} z(h - h) \nabla_x p^0 - (8\pi \eta)^{-1} \sum_{\alpha} \int_{S_{\alpha}} S_{\alpha}(x, x') t_l(x') dS',
\]

(10)

where the Green's function \( S_{\alpha} \) is symmetric, \( S_{\alpha}(x, x') = S_{\alpha}(x', x) \); see, e.g., Ref. [18]. This function is defined by \( u^\alpha(x) = S_{\alpha}(x, x_0) g_k/(8\pi \eta) \), where \( u^\alpha \) is the Stokeslet due to point force acting between two parallel plates,

\[
-\nabla p^\alpha + \eta \nabla^2 u^\alpha + g \delta(x - x_0) = 0, \quad \nabla \cdot u^\alpha = 0, \quad u^\alpha(z = 0) = u^\alpha(z = h) = 0,
\]

(11)

The function \( S_{\alpha} \) is independent of \( g \) and it was derived in Ref. [11]. We study the velocities \( V_\alpha \) by using the integral equation for the surface traction \( t(x) \). This equation is obtained by taking \( x \) in Eq. (10) to the surface of the spheres which gives

\[
(V_\alpha)_l + [\Omega_\alpha \times (x - x_\alpha)]_l = (2\eta)^{-1} \delta_{l\alpha} z(h - h) \nabla_x p^0 - (8\pi \eta)^{-1} \sum_{\alpha} \int_{S_{\alpha}} S_{\alpha}(x, x') t_l(x') dS',
\]

(12)

cf. Ref. [18]. This equation holds for all \( x \) on \( S_{\alpha} \) with \( \alpha = 1, 2 \). Together with the conditions of zero forces and torques it determines \( V_\alpha, \Omega_\alpha \) and the surface traction uniquely [2]. We use the assumption \( h \gg z_\alpha \), meaning that the wall at \( z = h \) is much further from the spheres than the one at \( z = 0 \). We can therefore approximately assume \( S_{\alpha}(x, x') \approx G_{\alpha}(x, x') \) where \( G_{\alpha}(x, x') \) is the Stokeslet near a plane wall defined by

\[
-\nabla p' + \eta \nabla^2 u' + g \delta(x - x_0) = 0, \quad \nabla \cdot u' = 0, \quad u'(z = 0) = u'(x \to \infty) = 0,
\]

(13)

The demand that \( S_{\alpha}(x, x') \approx G_{\alpha}(x, x') \) when both \( x \) and \( x' \) belong to the spheres quantifies the assumption that one of the walls is much further than the other. In practice the difference between distances to the upper and lower walls does not have to be too large for the equation to hold. With \( z_\alpha \ll h \) and this assumption, Eq. (12) becomes

\[
(V_\alpha)_l + [\Omega_\alpha \times (x - x_\alpha)]_l = \gamma \delta_{l\alpha} z - (8\pi \eta)^{-1} \sum_{\alpha} \int_{S_{\alpha}} G_{\alpha}(x, x') t_l(x') dS'.
\]

(14)
We introduce the decomposition of \(G_{il}(x, x')\) into the Stokeslet in an infinite space and the wall correction \(\tilde{G}_{il}\),

\[
G_{il}(x, x') = Y_{il}(r) + \tilde{G}_{il}(x, x'),
\]

with \(r = x - x'\), as above. The contribution \(\tilde{G}_{il}\) is induced by the images located at the reflection \((x)^* = (x', y', -z')\) of the source position \(x' = (x', y', z')\) with respect to the plane \(z = 0\). It was found in Ref. [19] that the image singularities are a point force of the same magnitude as the source, but with an opposite sign, a stokes-doublet, and a source-doublet, see definitions in the paper. We can write the formula in Ref. [19] as follows:

\[
\tilde{G}_{il}(x, x') = -Y_{il}(R) + 2z' \tilde{G}_{il}^{(1)}(R) + 2z'^2 \tilde{G}_{il}^{(2)}(R), \quad \tilde{G}_{il}^{(1)} = (2\delta_{il} - 1)\partial_i Y_{il},
\]

\[
\tilde{G}_{il}^{(2)} = \frac{(1 - 2\delta_{il})(R^2\delta_{il} - 3R_iR_l)}{R^5},
\]

where \(R = x - (x)^*\) is the distance from the images and there is no summation over repeated indices. The symmetries of the Green’s functions \(\tilde{G}_{il}(x, x') = \tilde{G}_{il}(x', x)\) and \(Y_{il}(x, x') = Y_{il}(x', x)\) imply the symmetry \(\tilde{G}_{il}(x, x') = \tilde{G}_{il}(x, x')\), which can be confirmed directly.

We compare Eq. (14) with the similar equation for two spheres driven by the unbounded shear flow that was considered above. The equation can be obtained by dropping \(\tilde{G}_{il}\) above, see Eq. (7), which yields

\[
(V_{il}^0)_i = \left[\Omega_{il}^0 \times (x - x_a)\right]_i = \gamma \delta_{il} z - (8\pi \eta)^{-1} \sum_{a'} \int_{S_{l'}} Y_{il}(x - x') \gamma_0^0(x') dS'.
\]

Subtracting Eq. (17) from Eq. (14) we find

\[
(\delta V_{il})_i + \left[\delta \Omega_{il} \times (x - x_a)\right]_i = (8\pi \eta)^{-1} \sum_{a'} \int_{S_{l'}} \tilde{G}_{il}(x, x') \gamma_0^0(x') dS'.
\]

Provided that \(\gamma_0^0(x)\) is known, this is an integral equation on \(\delta t(x)\) which also obeys the conditions of zero forces and torques given by Eqs. (2) with \(\delta t\) replacing \(t\). So far we have not made any approximations besides that the spheres are much closer to one of the two walls of the channel.

C. Asymptotic solution for a distant wall

We consider the solution of Eq. (18) in the limit of a distant wall. The last (source) term in the left hand side of this equation, in contrast with the rest of the terms, does not involve properties of \(\delta u\). If it is dropped, then we find Eq. (14) with \(\gamma = 0\), that is the equation for two inertialless spheres moving near the wall in the fluid at rest, which unique solution is trivial—zero translational and angular velocities.

In fact, Eq. (18) coincides with the equation for the velocities of an inertialless swimmer, composed of two spheres, that swims near a plane wall at \(z = 0\). In this case, the propulsion is powered by the swimming stroke prescribed by the velocity distribution at the spheres’ surface as given by that last term.

When both spheres are separated from the wall by a distance much larger than \(a\) the asymptotic series solution can be obtained via the Taylor expansion of \(\tilde{G}_{il}(x, x')\) near the centers of the spheres, cf. Sec. II A. Indeed, both arguments, \(x\) and \(x_a\), of \(\tilde{G}_{il}(x, x')\) are confined in Eq. (18) to one of the spheres (possibly different ones). In this range \(\tilde{G}_{il}(x, x')\) is a slowly varying function of its arguments because \(z_a \gg a\) and the image of \(x\) under this condition is separated from each sphere by a distance much larger than the radius, cf. with the Lorentz solution [1] and also the Appendix of Ref. [20].
This observation does not depend on the separation between the spheres that can be nonetheless arbitrary. Thus, we write Eq. (18) as
\[
(\delta V_\alpha)_i = [\delta \Omega_\alpha \times (x - x_\alpha)]_i + \sum_{\alpha'} \int_{S_{\alpha'}} \frac{\tilde{G}_{i\alpha}(x_\alpha, x'; t_0(\alpha)) dS'}{8\pi \eta} - (x - x_\alpha) \frac{\partial}{\partial x_k} \sum_{\alpha'} \int_{S_{\alpha'}} \frac{\tilde{G}_{i\alpha}(x, x'; t_0(\alpha)) dS'}{8\pi \eta} \bigg|_{x=x_\alpha} + \ldots
\]
where dots stand for higher-order terms in the Taylor expansion. The asymptotic solution can be obtained by requiring that the equation holds at every order in max[|a/z_1, a/z_2|] (the case of disparate \(z_\alpha\) seems to be of little interest so \(z_1 \sim z_2\) can be assumed below though this is not necessary for the analysis). The zero-order term determines the particle velocities,
\[
(\delta V_\alpha)_i = -\sum_{\alpha'} \int_{S_{\alpha'}} \frac{\tilde{G}_{i\alpha}(x_\alpha, x') \delta t_i(x') dS'}{8\pi \eta},
\]
where \(\delta t_i\) is zero at this order. This formula can be simplified by noting that \(\tilde{G}_{i\alpha}(x_\alpha, x')\) is a smooth function of \(x'\) on each of the spheres for the same reasons as before due to the symmetry \(\tilde{G}_{i\alpha}(x, x') = \tilde{G}_{i\alpha}(x', x)\). The zero-order term in the expansion vanishes by the condition of zero force. We thus find that
\[
\delta V_{\alpha i} = -\frac{S_{im}}{8\pi \eta} \sum_{\alpha'} \frac{\partial \tilde{G}_{i\alpha}(x_\alpha, x_{\alpha'})}{\partial (x_{\alpha'})_m} + o\left(\frac{a}{z_\alpha}\right),
\]
which is a more rigorous derivation of the result that might also be obtained using reflections as described in the beginning of the section. The use of an integral representation allows us to precisely formulate the validity conditions and to provide a transparent structure of the asymptotic series. It is important for the further analysis that the derivation does not assume any \(a\) priori relation between \(V_0^\alpha\) and \(\delta V_\alpha\). Actually, the absolute value of the velocities \(\delta V_\alpha\) would be smaller than \(V_0^\alpha\), however, this need not to be true for the relative velocities which are of main interest here.

**D. Evolution equation of interparticle distance**

The velocity of the relative motion of the spheres is described by \(V = V_2 - V_1\) that, at the leading order, obeys
\[
V_i = V_i^0 + \frac{S_{im}}{8\pi \eta} \sum_{\alpha'} \left[ \frac{\partial \tilde{G}_{i\alpha}(x_1, x_{\alpha'})}{\partial (x_{\alpha'})_m} - \frac{\partial \tilde{G}_{i\alpha}(x_2, x_{\alpha'})}{\partial (x_{\alpha'})_m} \right].
\]

The relative velocity in an unbounded shear flow \(V_0^i\) can be written as [4]
\[
V_i^0(r) = \gamma' \dot{z} \delta t_i - \dot{\gamma} B z \delta t_i - \frac{\dot{\gamma} B z \delta t_i}{2} - \frac{\dot{\gamma} (A - B) x z r_i}{r^2},
\]
where \(r = x_2 - x_1\). The first term in the right-hand side (RHS) is the driving shear flow. The remaining terms, due to hydrodynamic interactions, are described by the functions \(A\) and \(B\), which depend on \(|r| = r\) only. These functions are considered, similarly to \(K, L,\) and \(M\) above, as given [4]. We observe that \(V_0^i\) is determined uniquely by the distance between the particles and is independent of the particles’ center of mass. Thus, the evolution of \(r(t)\) without the wall is autonomous, i.e., the time derivative of \(r(t)\) is determined uniquely by the instantaneous value of \(r(t)\). We demonstrate that the evolution of \(r(t)\), described by Eq. (22), remains autonomous. This means that we can
neglect in \( V \), which is a function of \( x_i \), the dependence on the center-of-mass coordinate \((x_1 + x_2) / 2\). Since the horizontal coordinates of the center of mass are irrelevant by translational invariance in the horizontal directions, we need to consider only the dependence on \( z_0 = (z_1 + z_2) / 2 \). This coordinate would not change at all without the hydrodynamic interactions and the particles would move in straight lines parallel to the wall. The interactions cause temporal variations of \( z_0 \); however these occur only over the scale of these interactions which is the radius \( a \). Moreover, this change is small by the assumption that \( \max[a/z_1, a/z_2] \ll 1 \). This allows us to consider \( z_0 = (z_1 + z_2) / 2 \) as constant during the whole time of the interactions giving \( V = V[r(t), z_0(t)] \approx V[r(t), z_0(t_0)], \) where \( t_0 \) is arbitrary. For \( \delta V_i = V_i - V_i^0 \) we have

\[
\delta V_i = \frac{S_{lim}}{8\pi \eta} \sum_{\alpha} \left[ \frac{\partial \tilde{G}_{il}(x_{\alpha'}, x_1)}{\partial (x_{\alpha'})_m} - \frac{\partial \tilde{G}_{il}(x_{\alpha'}, x_2)}{\partial (x_{\alpha'})_m} \right]
\]

\[
= \frac{S_{lim}}{8\pi \eta} \sum_{\alpha} \frac{\partial}{\partial (x_{\alpha'})_m} \left[ Y_{il}(x_{\alpha'} - x_2^*) - Y_{il}(x_{\alpha'} - x_1^*) + 2z_1 G_{il}^1(x_{\alpha'} - x_1^*) + 2z_2 G_{il}^2(x_{\alpha'} - x_1^*) - 2z_2 G_{il}^1(x_{\alpha'} - x_1^*) - 2z_2^2 G_{il}^2(x_{\alpha'} - x_1^*) \right],
\]

(24)

where we used Eq. (16). The derivatives in the above equation can be written via the tensors

\[
T_{lim}^{(1)}(r) = -\frac{\partial Y_{il}(r)}{\partial r_m} = \frac{r^2(r_m \delta_{il} - r_l \delta_{im} - r_l \delta_{im}) + 3r_l r_m}{r^3};
\]

\[
T_{lim}^{(2)}(r) = \frac{\partial G_{il}^1}{\partial r_m} = (1 - 2\delta_{3l}) \left( \frac{\delta_{im} \delta_{3l} - \delta_{3l} \delta_{im} - \delta_{il} \delta_{3m}}{r^3} \right)
\]

\[
- \frac{3r_l (r_m \delta_{3l} - r_3 \delta_{im} - r_l \delta_{3m})}{r^5} + \frac{3(\delta_{il} r_l r_m + \delta_{im} r_3 r_m + \delta_{im} r_3 r_l)}{r^5} - \frac{15r_l r_3 r_m}{r^7};
\]

\[
T_{lim}^{(3)}(r) = -\delta_{il} \left( \frac{r_m \delta_{il} + \delta_{im} r_l + \delta_{im} r_i}{r^5} - \frac{5r_m r_i}{r^7} \right),
\]

(25)

where we used Eqs. (15) and (16). We also observe that

\[
x_{\alpha'} - x_{\alpha}^* = (x_{\alpha'} - x_\alpha, y_{\alpha'} - y_\alpha, z_{\alpha'} + z_\alpha).
\]

(26)

Thus, we find

\[
\delta V_i = \frac{S_{lim}}{8\pi \eta} \left[ K_{lim}^{11} - K_{lim}^{12} + K_{lim}^{21} - K_{lim}^{22} \right];
\]

\[
K_{lim}^{kn} = T_{lim}^{(1)}(x_k - x_{\alpha}^*) + 2z_j T_{lim}^{(2)}(x_k - x_{\alpha}^*) + 2z_j^2 T_{lim}^{(3)}(x_k - x_{\alpha}^*).
\]

(27)

We write above \( z_2 = z_0 + r_3 / 2 \) and \( z_1 = z_0 - r_3 / 2 \), where \( r_3 = z_2 - z_1 \) is the vertical component of the distance \( r \). We use \( x_{\alpha} - x_{\alpha}^* = 2z_\alpha \), so that

\[
T_{lim}^{(k)}(x_1 - x_{\alpha}^*) = T_{lim}^{(k)}(0, 0, 2z_0 - r_3); \quad T_{lim}^{(k)}(x_2 - x_{\alpha}^*) = T_{lim}^{(k)}(0, 0, 2z_0 + r_3).
\]

(28)

Similarly, using \( x_1 - x_{\alpha}^* = (-r_1, -r_2, z_1 + z_2) = (-r_1, -r_2, 2z_0) \) and \( x_2 - x_{\alpha}^* = (r_1, r_2, 2z_0) \), we find

\[
T_{lim}^{(k)}(x_1 - x_{\alpha}^*) = T_{lim}^{(k)}(-r_1, -r_2, 2z_0); \quad T_{lim}^{(k)}(x_2 - x_{\alpha}^*) = T_{lim}^{(k)}(r_1, r_2, 2z_0).
\]

(29)

The last equations provide the velocity in Eq. (27) in terms of \( r \) and \( z_0 \). We consider \( z_0 \) as a constant given by the initial configuration, see the discussion after Eq. (23). The remaining terms in Eq. (24) depend only on \( r \), providing an autonomous equation for \( r \).

The detailed form of the evolution equation for \( r \) in Cartesian coordinates is given by Eqs. (B1)–(B4) in Appendix B. The more compact form is found by employing the cylindrical coordinate system with \( x = \rho \cos \phi, y = \rho \sin \phi, z = z \). We find using the identities \( xx' + yy' = \rho \dot{\rho} \) and \(-yx' + \)
\[ xy = \rho^2 \phi \] and the definitions \( s^2 \equiv \rho^2 + 4z_0^2 \) and \( \sigma \equiv r^2 - s^2 \) that (here and below we set \( \dot{\gamma} = 1 \) by passing in the equation of motion for \( r \) to dimensionless time \( \dot{\gamma} \)),

\[
\dot{\rho} = z c_{\phi} \left[ 1 - \frac{B}{2} - \frac{\rho^2 (A - B)}{r^2} + \frac{5 \rho^2 P}{3 r^4 s^5} + \frac{10 z_0 R}{r^4 s^2} + \frac{5 \rho^2 \sigma}{2 r^4 s^7} (P + 2 (\rho^4 - s^2 \rho^2 + 4z_0^2 \rho^2) M) \right].
\] (30)

Here, we have introduced \( c_{\phi} = \cos \phi, P = r^2 x^2 (L - M) + 3 (\rho^4 + 4z_0^2 \rho^2) M \) and \( R = r^4 (1 + K + L) + 2z^2 \rho^2 M \); see definitions in Eqs. (9) and (23). The dynamics of \( c_{\phi} \) is

\[
\dot{c}_{\phi} = \frac{z}{\rho} \left( c_{\phi}^2 - 1 \right) \left[ \frac{B}{2} - 1 + \frac{5 \rho^2 \sigma L}{2 r^2 s^5} + \frac{10 z_0}{r^2 s^2} (r^2 (1 + K) + z^2 L) \right].
\] (31)

Finally, the dynamics of \( z \) reads

\[
\dot{z} = \rho c_{\phi} \left[ -\frac{B}{2} - \frac{z^2 (A - B)}{r^2} + \frac{5 (\rho^2 - 16z_0^2) \sigma R}{2 r^4 s^5} + \frac{5 \rho^2 P}{3 r^4 s^5} + \frac{10 z_0}{r^4 s^2} (r^2 L + 2z^2 - \rho^2 M) \right].
\] (32)

Further noting that \( \rho^4 - s^2 \rho^2 + 4z_0^2 z_0^2 = \rho^2 (\rho^2 - s^2) + 4z_0^2 z_0^2 = -4z_0^2 \rho^2 + 4z_0^2 z_0^2 = 4z_0^2 (z^2 - \rho^2) \), the evolution equation for \( \rho \) can be rewritten as

\[
\dot{\rho} = z c_{\phi} \left[ 1 - \frac{B}{2} - \frac{\rho^2 (A - B)}{r^2} + \frac{5 \rho^2 P}{3 r^4 s^5} + \frac{10 z_0 R}{r^4 s^2} + \frac{5 \rho^2 \sigma P}{2 r^4 s^7} + \frac{20 \rho^2 z_0^2 \sigma}{r^4 s^7} (z^2 - \rho^2) M \right].
\] (33)

It can be readily seen using \( |s| \sim z_0 \) and \( |\sigma| \sim z_0^2 \), that at fixed \( r \) we have \( \delta V_i \sim z_0^3 \) upon varying \( z_0 \). Similarly if we fix \( z_0 \) then \( \delta V_i \sim r^{-2} \) upon varying \( r \). The inverse cubic dependence on \( z_0 \) is nontrivial. Derivatives of \( \hat{G}_{ij}(r) \) contain terms of order \( r^{-2} \) which would give \( z_0^{-2} \) behavior in Eq. (21), cf. the dependence of \( T_{lim}^i \) on \( r \) in Eq. (25). Following rules for tensorial transformations upon the sign reversal of the argument, see, e.g., Eqs. (28) and (29), the leading order \( z_0^{-2} \) terms cancel.

We remark that finding the next order correction to \( V \) in the inverse distance to the wall would involve the quadratic surface moments originating from \( \theta^0 \). These were not considered previously and would be quite demanding to compute; see Eq. (20). It would also require considering the contributions in the second line of Eq. (19). The corresponding exceedingly complex calculations are beyond the scope of the present paper. We take here the practical approach of trying to push our leading order calculation to smaller \( z_0 \) and compare the analytical prediction with the results of the direct numerical simulations.

The equations of motion have symmetries that can be described as the properties of the velocity components,

\[
V_\rho (\rho, -\phi, z) = V_\rho (\rho, \phi, z), \quad V_\rho (\rho, \phi, -z) = -V_\rho (\rho, \phi, z), \quad V_\phi (\rho, -\phi, z) = V_\phi (\rho, \phi, z), \quad V_\theta (\rho, -\phi, z) = V_\phi (\rho, \phi, z), \quad V_\rho (\rho, \phi, -z) = V_\rho (\rho, \phi, z), \quad V_\phi (\rho, \phi, -z) = V_\phi (\rho, \phi, z).
\] (34)

These properties allow to confine the study of the trajectories \( r(t) \) to \( z \geq 0, \quad 0 \leq \phi \leq \pi/2 \), besides the constraint \( r \geq 2 \).

The main result of this section is the evolution equation for the distance between two spheres freely suspended in a shear flow near the wall,

\[
r = V(r) = V^0(r) + \delta V(r).
\] (35)

Here \( V^0(r) \), given by Eq. (23), describes hydrodynamic interactions due to shear in unbounded flow and \( \delta V \) describes the effects of the wall, given at the leading order by Eqs. (B1)–(B4). Despite that the wall is assumed to be distant, its effect is not small even for large channels.
that for a wall at infinite distance, the equilibrium point is dominated by the driving shear flow, see Eq. (23), and it is much larger than the other parameters: the hydrodynamic interactions are small by a/r whereas the interaction with the wall is small by a/z0. As a result at r given by a power of z0, whose exponent is determined by the details of the power laws of the particle-particle and particle-wall interactions, the interactions with the wall may dominate the evolution of r. The resulting topology of the trajectories of the relative motion is hence different, as we will describe in the following sections. First, we illustrate the differences numerically.

Trajectories that pass through points with y = 0 belong to the xz plane by symmetry, as V_c(y = 0) = 0. We consider the remaining components V_x and V_z as functions of x and z in the xz plane. We can restrict the analysis to positive x and z due to the symmetries described in the previous section. For the streamwise component of the velocity the wall is a regular perturbation: the ratio V_x/V_x^0 is everywhere close to 1. Thus, for z0 = 20 the maximal deviation of V_x/V_x^0 from 1 is seen numerically to be less than 1%. Consider for instance the ratio at x = y = 0 where the only nonzero components are V_x^0(0, 0, z) = (1 - B(z)/2)z and δV_x(0, 0, z) = 10z_0|1 + K(z) + L(z)|/(z^2 - 4z_0^2)^2, see Eqs. (23) and (B1). When z ~ 2 all B(z), K(z), L(z) are finite and less than unity [4]. By taking the ratio we find that δV_x/V_x^0 ~ 10/z_0^2 ≪ 1 at z0 ≫ 1. At large distances V_x^0 is dominated by the driving shear flow, see Eq. (23), and it is much larger than δV_x because the symmetry imposes proportionality of δV_x and z, see Eq. (B1). Similarly, in other cases, V_c/V_c^0 ≈ 1. Thus, for practical purposes we can set

$$V_x(r) \approx V_x^0(r) = \left[1 - \frac{B(r)}{2}\right]z - \frac{[A(r) - B(r)]x^2z}{r^2},$$

(36)

which at large distances reduces to the carrying shear flow difference given by z. The situation is quite different for V_z/V_z^0 in Fig. 7. We see that when the spheres are close, the difference is negligible and V_z ≈ V_z^0. However, the situation is quite different at large separations. From Eq. (23) we obtain that for a wall at infinite distance,

$$V_z^0(r) = -\frac{Bx}{2} - \frac{(A - B)xz^2}{r^2},$$

(37)

FIG. 7. The ratio V_z/V_z^0 for z0 = 20 (a) in the xz plane and (b) along the x axis. The presence of the wall increases the velocity at x ≫ z0 by a constant large factor of order z_0^2. The two critical points are the neutral equilibrium point r_c = 4z0 = 80 and the saddle point r_s = (32z_0^3/15)^1/5 [see the inset in (b)].

III. SINGULAR EFFECT OF THE WALL AT FAR DISTANCES

In this section we demonstrate that the wall is a singular perturbation of the relative motion between the two spheres. Regardless of how large z0 is, its influence cannot be entirely neglected. For any fixed r we have V(r) = V^0(r) for z0 → ∞. However, for any fixed z0 ≫ 1 there are large r for which some velocity components satisfy |δV_i| ≫ V_i^0. There is a competition between the different parameters: the hydrodynamic interactions are small by a/r whereas the interaction with the wall is small by a/z0. As a result at r given by a power of z0, whose exponent is determined by the details of the power laws of the particle-particle and particle-wall interactions, the interactions with the wall may dominate the evolution of r. The resulting topology of the trajectories of the relative motion is hence different, as we will describe in the following sections. First, we illustrate the differences numerically.

Trajectories that pass through points with y = 0 belong to the xz plane by symmetry, as V_y(y = 0) = 0. We consider the remaining components V_x and V_z as functions of x and z in the xz plane. We can restrict the analysis to positive x and z due to the symmetries described in the previous section. For the streamwise component of the velocity the wall is a regular perturbation: the ratio V_x/V_x^0 is everywhere close to 1. Thus, for z0 = 20 the maximal deviation of V_x/V_x^0 from 1 is seen numerically to be less than 1%. Consider for instance the ratio at x = y = 0 where the only nonzero components are V_x^0(0, 0, z) = (1 - B(z)/2)z and δV_x(0, 0, z) = 10z_0|1 + K(z) + L(z)|/(z^2 - 4z_0^2)^2, see Eqs. (23) and (B1). When z ~ 2 all B(z), K(z), L(z) are finite and less than unity [4]. By taking the ratio we find that δV_x/V_x^0 ~ 10/z_0^2 ≪ 1 at z0 ≫ 1. At large distances V_x^0 is dominated by the driving shear flow, see Eq. (23), and it is much larger than δV_x because the symmetry imposes proportionality of δV_x and z, see Eq. (B1). Similarly, in other cases, V_c/V_c^0 ≈ 1. Thus, for practical purposes we can set

$$V_x(r) \approx V_x^0(r) = \left[1 - \frac{B(r)}{2}\right]z - \frac{[A(r) - B(r)]x^2z}{r^2},$$

(36)

which at large distances reduces to the carrying shear flow difference given by z. The situation is quite different for V_z/V_z^0 in Fig. 7. We see that when the spheres are close, the difference is negligible and V_z ≈ V_z^0. However, the situation is quite different at large separations. From Eq. (23) we obtain that for a wall at infinite distance,

$$V_z^0(r) = -\frac{Bx}{2} - \frac{(A - B)xz^2}{r^2},$$

(37)
which can be further simplified at large \( r \) using

\[
A(r) = \frac{5}{r^3} + O\left( \frac{1}{r^3} \right), \quad B(r) = \frac{16}{3r^3} + o\left( \frac{1}{r^6} \right);
\]

see Ref. [4]. We thus find that

\[
V_z^0(r) \approx -\frac{8x}{3r^5} - \frac{5xz^2}{r^5},
\]

which is negative at \( x > 0 \). We observe from Eqs. (38) that the order of corrections is quite high so this formula might hold already at \( r \gtrsim 3 \cdot 4 \). For \( \delta V_z \) we have from the equations in Appendix B that

\[
\delta V_z(x, 0, 0) = \frac{10|xz_0^2(16z_0^2 - x^2)|}{(x^2 + 4z_0^2)^{7/2}} \left[ 1 + K(x) + L(x) \right].
\]

This can be simplified at large \( x \) following Ref. [4],

\[
K(r) \approx -\frac{2}{r^5}, \quad L(r) \approx -\frac{5}{2r^5}, \quad M(r) \approx \frac{25}{2r^5}, \quad r \gg 1,
\]

by neglecting \( K \) and \( L \) compared to unity in Eq. (40). These functions decay fast with \( r \), implying that

\[
\delta V_z(x, 0, 0) \approx \frac{10|xz_0^2(16z_0^2 - x^2)|}{(x^2 + 4z_0^2)^{7/2}}.
\]

must hold already at \( x = 3 \) where the spheres are rather close. We also find for the ratio of velocities

\[
\frac{\delta V_z(x, 0, 0)}{V_z^0(x, 0, 0)} = \frac{15x^5z_0^2(x^2 - 16z_0^2)}{4(x^2 + 4z_0^2)^{7/2}}; \quad x \gg 1.
\]

The corrections are of order higher than \( 1/x \) so in practice this formula works at rather small \( x \).

The ratio on the left-hand side of Eq. (43) equals \(-1\) at \( x \) obeying the condition

\[
15x^5z_0^2(x^2 - 16z_0^2) + 4(x^2 + 4z_0^2)^{7/2} = 0.
\]

This equation has two solutions. The first one is obtained when \( x \ll 2z_0 \) and hence \( 15x^5 = 32z_0^3 \) leading to \( r_c = (32z_0^3/15)^{1/3} \). This expression for the critical point, obtained from the \( x \gg 1 \) approximation given by Eq. (43), is indistinguishable from the numerical solution of \( V_z(x, 0, 0) = 0 \) with the full velocity given by Eqs. (B1)–(B4), at least down to \( z_0 = 5 \) which is the smallest \( z_0 \) considered in this work (we have \( r_c \approx 3 \) at \( z_0 = 5 \)). This is reasonable in view of the remarks after Eqs. (39), (42), and (43). To find the other solution we notice that \( x^2 = 16z_0^2 + \delta \) with \( \delta \ll 16z_0^2 \) solves the equation giving \( r_c \approx 4z_0 \). Both \( r_c \) and \( r_r \) are much larger than unity at \( z_0 \gg 1 \) confirming the consistency of the approach and can be used for \( z_0 \gtrsim 5 \).

The obtained points obey \( V_z(r_c, 0, 0) = V_z(r_r, 0, 0) = 0 \). Moreover, \( V_z(x, 0, 0) = V_z(x, 0, 0) = 0 \) since both \( V_\delta(x, y, z) \) and \( V_\gamma(x, y, z) \) are odd functions of \( z \); see Eq. (B5). Thus, the points on the \( x \) axis with \( x = r_c \) and \( x = r_r \) are the critical points with \( V = 0 \). We demonstrate below that these are a saddle point and a stationary point, respectively.

Finally, we would like to emphasise the singular nature of the perturbation due to the long-range interaction at finite \( z_0 \). For motions in the plane \( y = 0 \), at large but finite \( z_0 \), there are locations \( r \) for which the wall-normal component of the velocity \( V_z \) is much larger than the BG velocity, see the \( z_0 = 20 \) case in Fig. 7. In fact, for \( x \gg z_0 \), the ratio \( \delta V_z(x, 0, 0)/V_z^0(x, 0, 0) \) becomes an \( x \)-independent constant of order \( z_0^2 \gg 1 \). The wall contribution to the velocity is opposite in sign to the BG velocity. If we consider two particles on the same streamline of the unperturbed flow with
y = z = 0, then the only nonvanishing, z component of the velocity $V_z(x, 0, 0)$ is

$$V_z = \frac{10x_0^2(16z_0^2 - x^2)}{(x^2 + 4z_0^2)^{7/2}}[1 + K(x) + L(x)] - \frac{xB(x)}{2}. \quad (45)$$

In the BG limit of $z_0 \to \infty$, taken at fixed $x$, the first term drops, reducing the velocity to $V_z^0(x, 0, 0) = xB(x)/2$, see Eq. (37), and at large distances $xB(x)/2 \approx 8/(3x^4)$, see Eq. (38). In contrast, at any finite $z_0$, for $x \gg z_0$, the range not considered in the BG approximation, the contribution due to the wall, described by the first term in Eq. (45) behaves as $z_0^2 x^{-4}$. We find, using that the functions $K(x)$ and $L(x)$ vanish at large distances by Eq. (41),

$$\lim_{x \to \infty} \frac{\delta V_z(x, 0, 0)}{V_z^0(x, 0, 0)} = \lim_{x \to \infty} \frac{20z_0^2(x^2 - 16z_0^2)}{B(x)(x^2 + 4z_0^2)^{7/2}} = \frac{15z_0^2}{4}. \quad (46)$$

Thus, the interaction between particles flowing along the same streamline is dominated by the wall term at $x \gtrsim z_0$. This sets in nonuniformly. We see from Fig. 7(b) that for $z_0 = 20$ the absolute value $|V_z(x, 0, 0)/V_z^0(x, 0, 0)|$ grows fast with $x$. It crosses zero (which corresponds to $|\delta V_z(x, 0, 0)/V_z^0(x, 0, 0)| = 1$) at the critical saddle point $(32z_0^3/15)^{1/5} \approx 7$, a value smaller than the half of $z_0$. One might have expected that $r \lesssim z_0$ guarantees at least a qualitative validity of the BG theory, however, it does not. The ratio $|\delta V_z(x, 0, 0)/V_z^0(x, 0, 0)|$ rapidly grows with $x$, becoming of order one hundred already at $x \approx 30$. However, after reaching the maximum, it decreases to the value 1 at the critical point at $x = 4z_0$. Only at $x \gg 4z_0$ the asymptotic law $|V_z(x, 0, 0)/V_z^0(x, 0, 0)| \sim z_0^2$ starts to apply. We find numerically that the curve $|V_z(x, 0, 0)/V_z^0(x, 0, 0)|$ starts flattening at $x \sim 200$ when its value is about one thousand. The approach to the limiting value of 1500, imposed by Eq. (46), is quite slow: e.g., at $x \approx 450$ the ratio is about 1400. We conclude that, at the considered value of $z_0$, the wall dominates the interactions at all $x \gtrsim z_0/2$, excluding a small neighborhood of the neutral equilibrium critical point $r_s$.

The strong changes of $V$ induced by the presence of a wall described in this section imply that the phase portrait is very different from that obtained in the limit $z_0 \to \infty$. In the next section, we therefore start from reviewing the reference $z_0 = \infty$ case.

IV. TRAJECTORIES FOR INFINITELY DISTANT WALLS

We describe briefly the seminal results in Ref. [4] pertaining the relative motion of two spheres in unbounded shear flow, as determined by the equation of motion $\dot{r} = V^0(r)$. The trajectories can be obtained from the two integrals $R_2$ and $R_3$ (notice a different labeling of the axes compared to Ref. [4]; we have $y$ and $z$, and accordingly $R_2$ and $R_3$, switched):

$$R_2 = y \exp \left[ \int_r^\infty \frac{B(r') - A(r')}{1 - A(r')} \, dr' \right],$$

$$R_3^2 = z^2 \exp \left[ 2 \int_r^\infty \frac{B(r') - A(r')}{1 - A(r')} \, dr' \right] - \int_r^\infty \frac{B(r')}{1 - A(r')} \, dr' \exp \left[ 2 \int_r^\infty \frac{B(r'')}{1 - A(r'')} \, dr'' \right]. \quad (47)$$

We consider trajectories in the symmetry $xz$ plane ($y = 0$) where $R_2 = 0$. The trajectories are given in the form $z = z(r)$ where $(r^2 = x^2 + z^2)$,

$$z^2(r) = R_3^2 \exp \left[ 2 \int_r^\infty \frac{A(r') - B(r')}{1 - A(r')} \, dr' \right] + \int_r^\infty \frac{B(r')}{1 - A(r')} \, dr' \exp \left[ 2 \int_r^\infty \frac{A(r'') - B(r'')}{1 - A(r'')} \, dr'' \right]. \quad (48)$$

There are two types of trajectories: open and closed trajectories corresponding to $R_3^2 > 0$ and $R_3^2 < 0$, respectively. The regions in phase space occupied by open and closed trajectories are separated.
by the separatrix \( z^s(r) \) whose equation is found by setting \( R_3 = 0 \),

\[
(z^s)^2 = \int_r^\infty \frac{B(r')r'dr'}{1-A(r')} \exp \left[ 2 \int_r^{r'} \frac{A(r'') - B(r'')} {1 - A(r'')} \frac{dr''} {r''} \right]. \tag{49}
\]

We can obtain \( z^s(r) \) at large \( r \) using Eq. (38),

\[
\int_r^{r'} \frac{A(r'') - B(r'')} {1 - A(r'')} \frac{dr''} {r''} \approx \int_r^{r'} \frac{5dr''} {r''} \approx \frac{5} {3} \left( \frac{1} {r^3} - \frac{1} {r'^3} \right).
\]

The separatrix equation becomes (this asymptotic form was not presented in Ref. [4]),

\[
(z^s)^2 \approx \exp \left( \frac{10} {3r^3} \right) \int_r^\infty \frac{16dr'} {3r'^4} \exp \left( -\frac{10} {3r'^3} \right) = \frac{8} {15} \left[ \exp \left( \frac{10} {3r^3} \right) - 1 \right] \approx \frac{16} {9r^3} \approx \frac{16} {9s^3}, \tag{50}
\]

which shows that the separatrix asymptotically approaches the \( x \) axis [6]. The surface obtained by rotation of this curve around the \( z \) axis separates closed and open three-dimensional trajectories. The volume of closed trajectories is infinite due to divergence of two dimensional integral of \((x^2 + y^2)^{-3/2}\).

We could not obtain a description of the particle-pair motion by integrals similar to \( R_2 \) and \( R_3 \) in the presence of the walls. For some trajectories, however, the wall is a small perturbation so that \( V(r) \approx V^0(r) \) holds everywhere along the trajectory. The trajectory equation is then \( x(t) = x^0(t) + \delta x(t) \) where \( x^0(t) \) is a BG trajectory and \( \delta x(t) \) represents just a small modification. An example of these trajectories is the trajectory \( a \) in Fig. 11. These trajectories can be described with integrals of motion \( R_i = R_i^0 + \delta R_i \) where \( \delta R_i \) is a small perturbation of the functional form of the \( R_i \) due to the wall. This perturbation can be found from perturbation theory. However, this is of limited use since we are interested in trajectories for which the wall contribution is not small.

### V. Trajectories for a Wall at Finite Distance

Here, we present the results of numerical simulations of the evolution equation of the interparticle distance obtained in Sec. IID. We apply the algorithm proposed in Ref. [21], which allows us to compute the hydrodynamic interactions in a system of \( N \) spheres in a creeping flow. The algorithm is based on the multipole expansion of the Lamb solution for the fluid velocity field. We applied it to describe the motion in a system of two force- and torque-free solid spheres of unit radius in a shear flow for different distances \( r \) between the centers. Namely, for given components of the shear flow field and the vector \( r \) connecting the sphere centers, we compute the velocity \( V \) in Eq. (22). Thus, we determined the functions \( A, B, K, L, \) and \( M \) for \( r \geq 2.01 \) using the formulas in Ref. [4]. When \( r \) approaches the value \( r = 2 \) the algorithm requires a very large number of spherical harmonics into the solution expansion, which leads to a very large system of linear equations for the coefficients of the harmonics.

The functions \( A \) and \( B \) were therefore smoothly continued to \( r = 2 \) using the asymptotic forms for almost touching spheres given by

\[
A(r) = 1 - 4.077(r - 2) + O((r - 2)^{3/2}), \quad B \approx 0.406 - \frac{0.78} {\ln[(r - 2)^{-1}]}.
\tag{51}
\]

The derivative of \( B \) diverges at \( r = 2 \), while the functions \( A, K, L, \) and \( M \) are finite in the limit of touching spheres, \( r \to 2 \) and can be continued from \( r \geq 2.01 \) to \( r < 2.01 \) using a linear Taylor series approximation. A similar approach was used in Ref. [5], where, however, continuation was used only below 2.0002. Our main interest is in the behavior at larger \( r \) so we did not undertake the detailed solution for the small values of \( r - 2 \). A higher resolution is needed for the precise evaluation of the impact of the wall on the nearly touching BG trajectories and is left for future work.
FIG. 8. The phase portrait in the $xz$ plane for $z_0 = 5$ (a) and $z_0 = 10$ (b). The BG separatrix obeying $z^2 = 16/(9r^3)$ at large $x$ is depicted by the dashed (grey) line. For any finite $z_0$, the phase portrait contains two disconnected regions of closed trajectories, in contrast to one region at $z_0 = \infty$. Region I, where all trajectories are closed and the spheres are close to each other, is similar to that at $z_0 = \infty$. Region II is also similar to the $z_0 = \infty$ case: all the trajectories are open and the vertical separation after the interaction returns to its original value. Region III has no counterpart at $z_0 = \infty$. This region contains both closed and open trajectories (see Fig. 12 for a more detailed description). The trajectories passing not far from the stationary point $r_c$ are closed, orbiting around this point. The swapping open trajectories instead are characterized by a sign reversal of the vertical component of the separation vector after the encounter. The region of swapping trajectories is bounded from one side by the closed trajectories around $r_c$ and from the other side by open nonswapping trajectories.

Here, the equations of motion are generated employing the velocities given by the contributions Eqs. (23) and (27). These equations are solved numerically using the custom code in Mathematica, which reduces the integration step when the trajectory approaches the vicinity of $r = 2$. In this region, the different trajectories are very close to each other and one has to resolve them accurately. This necessity is obvious already from the BG trajectories in the symmetry plane. All trajectories when the spheres pass in close vicinity to $r = 2$ are closed. In other words, the trajectories that cross the $z$ axis at $z$ obeying $2 \leq z \leq 2 + \Delta$ are closed; however, those crossing at $z > 2 + \Delta$ are open where $\Delta$ is a small number. The quantity $\Delta$ obeys the equation

$$
(2 + \Delta)^2 = \int_{2+\Delta}^{\infty} \frac{B(r') r' dr'}{1 - A(r')} \exp \left[ 2 \int_{2+\Delta}^{r'} \frac{A(r'') - B(r'') dr''}{1 - A(r'')} r'' \right],
$$

as readily seen from Eq. (49). The evaluation of $\Delta$ from this equation (not done in Ref. [4]) is beyond our scope here. Note, however, that Ref. [5] provide $\Delta \sim 10^{-5}$.

The smallness of $\Delta$ implies that small perturbations can readily turn closed trajectory into an open one, which is indeed what the distant wall does as shown in Fig. 8. The resolution of these small-scale effects demands high numerical precision.

To construct the separatrices (defined here as curves separating regions of qualitatively different behavior) in the $xz$ plane for given value of $z_0$ we first find the critical point on the $x$ axis $(r_s, 0, 0)$ where the approximate value of $r_s$ is given in Sec. III. One separatrix (red curve in Fig. 8) is stable, see Fig. 3 and thus is computed using integration of the original equations. The other separatrix (blue curve in Fig. 8) is unstable as seen from Fig. 3. Thus, it is found by backward integration in time, for which it is stable, until the trajectory reaches the $z$ axis. All the trajectories below the blue
curve (region I) are closed, while those between the red and blue curves (region II) are open—they correspond to nonswapping trajectories. The trajectories between the red curve and the x axis (region III) can be divided into two classes—open swapping trajectories (brown, black curves in the inset of Fig. 12) and closed trajectories characterized by a very large separation between the spheres (green, blue curves), see the captions of the Figures and detailed theory in the next section.

We next consider three-dimensional trajectories. The axial symmetry of the governing Eqs. (30)–(32) implies that the saddle points reside in the xy plane on a circle with radius \( r_s \). For each point on this curve one can construct the corresponding separatrices in 3D (see Fig. 9, where the third neutral direction is given by the circle \( r = r_c \), not shown). All the separatrices belong to some surface of rotation (Fig. 10) which is obtained by the rotation of the curves in Fig. 12 around the z axis.

At this point, it is instructive to compare the evolutions of the same representative initial conditions for \( z_0 = \infty \) and finite \( z_0 \). The evolution of conditions that produce closed BG trajectories with small \( x^2 + z^2 \) in the limit \( z_0 = \infty \) is only weakly influenced by far wall (unless passing near the BG separatrix where small perturbations are relevant), as in Fig. 6, see the caption. In contrast, the trajectories with large \( x^2 + z^2 \) may be very different as shown in Fig. 5 where the wall changes the evolution from an open trajectory to a closed one. The evolution of initial conditions leading to open trajectories for \( z_0 = \infty \) may be only slightly changed by the wall, as in Fig. 11(a), or result in swapping as for the case in Fig. 11(b).

VI. THEORY OF DANCING-SWAPPING REGION

In this section we analyze the trajectories in the dancing-swapping region III, as shown in Figs. 8. We restrict the consideration to the symmetry plane \( y = 0 \). All trajectories in this region cross the x axis. These trajectories are of two types, both are qualitatively different from the BG theory. The swapping trajectories are open, each crosses the x axis at a single point \( x \) obeying \( r_s < x < x_s \) where \( r_s = (32z_0^3/15)^{1/5} \) and \( x_s = 2\sqrt{2}z_0 \) is determined below. For these trajectories the difference of the
FIG. 10. Surface of rotation formed by the separatrices that pass through \((r, \cos \phi, \sin \phi, 0)\) with \(0 \leq \phi \leq 2\pi\) at \(z_0 = 20\). The green curves represent separatrices corresponding to \(\phi = 0, \pi / 36, \pi / 18, 5\pi / 36, \pi / 4\). The trajectories inside the region formed by the blue surface are closed BG-type orbits, whereas the trajectories inside the orange surface are either open swapping or closed dancing trajectories, as in region III in Fig. 12, cf. Fig. 9.

\(z\) coordinates of the particles changes sign as a result of the hydrodynamic encounter (as for black curve in Fig. 12). This sign-reversal corresponds to swapping of the vertical coordinates, see the Introduction. The larger crossing coordinate is, starting from \(x = r_x\), the closer the trajectory is to the \(x\) axis at large \(x\). For the unique trajectory passing through \(x = x_s\), the trajectory asymptotically approaches the \(x\) axis indefinitely similarly to the BG’s separatrix, dividing regions of open and

FIG. 11. Comparison of representative open trajectories in the BG case (red) and in the case of a wall at a finite distance \(z_0 \) (blue): (a) typical open trajectories are qualitatively similar in both cases \((z_0 = 20)\); (b) for some initial conditions the presence of the wall results in the appearance of a swapping trajectory \((z_0 = 5)\). The black arrows indicate the direction of motion.
FIG. 12. The dancing-swapping region III of Figs. 8 for \( z_0 = 20 \). The red line is the region’s boundary that crosses the \( x \) axis at \( (32z_0^3/15)^{1/5} \). The dashed blue line separates open swapping and closed dancing trajectories and crosses the \( x \) axis at \( x_s = 2\sqrt{2}z_0 \). The black dot is the equilibrium point \( (r_c = 4z_0, 0) \).

closed trajectories. Finally, the trajectories that pass through a point \((x > x_s, 0, 0)\) are closed, each crossing the \( x \) axis at two locations.

First we observe that the evolution of trajectories in the dancing-swapping region III admits \( r \gg 1 \) and thus can be simplified. It is readily seen numerically that, at least for \( z_0 \geq 5 \) that are of interest here, we have \( V^0(r) \approx z \) within less than 15% accuracy, meaning that the BG velocity difference is fully determined by the undisturbed shear flow. This is because the hydrodynamic interactions’ correction to \( V^0(r) \) decays quickly with the spheres’ separation, see Eqs. (36) and (38). We find from Eq. (36) that we can use \( V_s(r) \approx z \) everywhere in region III. Moreover, we observe that \( \delta V_z(x, 0, z) - \delta V_z(x, 0, 0) \) grows quadratically with \( z \); see Appendix B. It is then found that since small-\( z \) approximation holds (see below) then we can then use \( \delta V_z(x, 0, z) \approx \delta V_z(x, 0, 0) \) in the whole region III. Finally, we can use the reduced Eq. (42). We find that the evolution of the trajectories in region III can be accurately described by the reduced system of equations,

\[
\begin{align*}
\dot{x} &= z, \\
\dot{z} &= -\frac{8x}{3r^5} - \frac{5xz^2}{r^5} + \frac{10xz_0^2(16z_0^2 - x^2)}{(x^2 + 4z_0^2)^{7/2}},
\end{align*}
\]

(53)

where we assumed \( z_0 \geq 5 \) and used Eq. (39). Furthermore, since region III is characterized by small \( z \) then it is seen that \( r \approx x \) and the second term in the RHS of the equation on \( z \) can be dropped. Indeed, the ratio \( 15z_0^2/8 \) of this term to the first term in the RHS is small at moderate \( x \) and not so small at larger \( x \). However, at larger \( x \) the time-derivative \( \dot{z} \) is determined by the third term. Thus, the second term is uniformly small everywhere in III as we verified numerically, and Eq. (53) is rewritten as

\[
\begin{align*}
\dot{x} &= z, \\
\dot{z} &= -\frac{8x}{3x^4} + \frac{10xz_0^2(16z_0^2 - x^2)}{(x^2 + 4z_0^2)^{7/2}}.
\end{align*}
\]

(54)
The trajectories produced by this system in region III are indistinguishable from those produced by the full $V(r)$. The critical points of this approximate evolution obviously coincide with those obtained in Eq. (44), so that, e.g., $10r_3z_0^2(16z_0^2 - r_s^2)/(r_s^2 + 4z_0^2)^{3/2} = 8/(3r_s^4)$ with $r_s = (32z_0^3/15)^{1/5}$. Eliminating time variable we arrive at

$$\frac{d}{dx}z^2 = -\frac{16}{3x^4} + \frac{20xz_0^2(16z_0^2 - x^2)}{(x^2 + 4z_0^2)^{7/2}}.$$  \hspace{1cm} (55)

The trajectory that crosses the $x$ axis at $x = x_i$ is given by the solution of the above equation and it reads

$$z^2 = \frac{16}{27x^3} + \frac{20z_0^2(x^2 - 8z_0^2)}{3(x^2 + 4z_0^2)^{5/2}} - \frac{16}{27x_i^3} - \frac{20z_0^2(x_i^2 - 8z_0^2)}{3(x_i^2 + 4z_0^2)^{5/2}}.$$  \hspace{1cm} (56)

Setting here $x_i = r_s$ and using the condition on $r_s$ provided after Eq. (54), we arrive at the equation of the separatrix bounding the dancing-swapping region and separating it from region II (red line in Fig. 8)

$$z_{II,III}^2 = \frac{16}{27x^3} + \frac{20z_0^2(x^2 - 8z_0^2)}{3(x^2 + 4z_0^2)^{5/2}} + \frac{40z_0^2(48z_0^4 - 20r_s^2z_0^2 - r_s^4)}{9(r_s^2 + 4z_0^2)^{7/2}}, \quad \text{at } r_s = \left(\frac{32z_0^3}{15}\right)^{1/5}. \hspace{1cm} (57)

We further find the following asymptotic behavior

$$z_{II,III}^2(x = \infty) = \frac{40z_0^2(48z_0^4 - 20r_s^2z_0^2 - r_s^4)}{9(r_s^2 + 4z_0^2)^{7/2}} \approx \frac{5}{3z_0}, \hspace{1cm} (58)$$

where the first equality holds down to $z_0 = 5$ and the last equality assumes $z_0 \gg 1$. The equations confirm that region III has a finite width in $z$-direction, the fact underlying the validity of $\delta V_{\epsilon}(x, 0, z) \approx \delta V_{\epsilon}(x, 0, 0)$. The last equality provides the scaling law of growth of region III as the proximity to the wall decreases from $z_0 = \infty$ to some finite value.

There is a unique value of $x_i = x_i$ for which the last two terms in Eq. (56) vanish and the trajectory asymptotes the $x$ axis at large $x$. This value is determined by the condition $x_i^3 = 4(x_i^2 + 4z_0^2)^{5/2}/(45z_0^2(8z_0^2 - x_i^2))$. The solution is $x_i^2 = 8z_0^2 - \epsilon$ with $\epsilon \approx 8\sqrt{3}/(5\sqrt{2})$. The corresponding trajectory $z_{sw}$ is the separatrix of swapping and dancing trajectories,

$$z_{sw}^2 = \frac{16}{27x^3} + \frac{20z_0^2(x^2 - 8z_0^2)}{3(x^2 + 4z_0^2)^{5/2}}; \quad z_{sw}^2(x = 2\sqrt{2z_0}) = 0. \hspace{1cm} (59)$$

This asymptotic behavior of this separatrix at $x \gg z_0$ is $z_{sw}^2 \approx 20z_0^2/(3x^3)$. Remarkably, this is the same behavior as the BG asymptote given by Eq. (50), however, with a much larger coefficient. Since the three-dimensional separatrix is obtained by revolution around the $z$ axis, we conclude that the volume of closed dancing trajectories is infinite. Thus, the wall does not regularize the divergences in the stress calculation at the second order in concentration of Ref. [15]. The volume of swapping trajectories is also infinite. Finally, we remark that long-distance behavior of trajectories in regions I and II can also be described using the approach of this section; however, the global behavior in those regions involves close positions of the spheres and demands the full formulas.

VII. DIRECT NUMERICAL SIMULATION OF A PARTICLE PAIR IN POISEUILLE FLOWS

In this section we provide supporting evidence of the existence of the neutral equilibrium point $(r_s, 0, 0)$ from direct numerical simulations of the motion of a pair of particles in the Poiseuille flow. We simulate the Navier-Stokes equations with appropriate boundary conditions at a Reynolds number of 0.1 to approximate solutions of Stokes flows, as verified in previous work [12,22]. A moderate distance from the wall ($z_0 = 5$) is considered to examine the accuracy of the theory in...
TWO SPHERES IN WALL-BOUNDED SHEAR FLOW

conditions typical of microfluidic channels, cf. Refs. [9,10]. In this way, we provide confirmation of
the theory and demonstrate that it holds down to rather small \( z_0 \).

There is a number of methods for the numerical simulation of particle motion in viscous flows,
one of the most popular is Stokesian dynamics [23] that has been recently adopted for wall-bounded
flows [16,17]. Within this method the boundary integrals in Eq. (10) are expanded in infinite
series of multipoles. Truncation of the series, which is valid at large interparticle and particle-wall
distances is typically done at the stresslet level and produces an approximation to the flow from
which the particles’ velocities are derived using Faxén’s laws. The pairwise additive near-field
hydrodynamics is included explicitly by using the results of the lubrication theory [23], thereby
providing expressions that interpolate between the correct large- and small-distance hydrodynamics.
This is a powerful method particularly suitable for numerical analysis of many-particle systems.
Since we are only concerned with interactions of just two particles, the direct approach seems more
applicable. We therefore use interface-resolved, direct numerical scheme to obtain motions of the
particles and full solution of the ambient flow field. The particles are simulated either as solid
spheres using an immersed boundary method or as liquid droplets using the interface-correction
level set/ghost fluid method; see Refs. [10,22,24] and the Appendix B of Ref. [12] for detailed
descriptions of the governing equations and their numerical treatments. Note that, our computational
scheme does not neglect any details (up to the numerical precision) of the fluid motion throughout
a suspension, hence it is better suited for detailed studies of few hydrodynamically interacting
particles despite being computationally more expensive, cf. Ref. [16].

Figure 1 illustrates the schematic of the simulation setup. Here, two neutrally buoyant particles
are transported inside a rectangular channel of dimensions \( L_x \), \( L_y \), and \( L_z \), that are at least an order-
of-magnitude larger than the particle radius \( a \). The undisturbed flow is the Poiseuille flow shifted
backwards by a constant velocity so that the position of the first particle remains roughly unchanged
throughout the simulation [25]. The particle pair is initially placed adjacent to the bottom wall,
with \( z_0 = 5 \) and \( L_z = 64 \). \( L_x \) and \( L_y \) are chosen to be large enough so that the imposed boundary
conditions (periodic or inflow/outflow) do not qualitatively affect the particle motion, which we
verified by checking that changes in \( L_x \) and \( L_y \) do not affect the results appreciably. Thus, we used
\( L_x = 12 \) and 24, and increased \( L_y \) from 60 up to 80.

Figure 13 depicts the vertical component of the relative velocity \( V_z \) of two solid particles at
various initial separations \( r/z_0 \), obtained asymptotically upon their release. That is, we extract \( V_z \)
from the simulations when both particles are still approximately at the same vertical position \( z_0 \)
within the accuracy of \( 10^{-4} \). The theoretical values are computed according to Eqs. (39) and (43),
which apply since the minimal considered distance is 15. Remarkably, we observe a close agreement
between the theoretical prediction and the numerical simulation, from the smallest studied distance
of \( r = 3z_0 \). This is despite that the simulations are performed in a pressure-driven channel flow in
the presence of two walls and \( z_0 \) is not so large. The deviation of the numerical results from the
theoretical values at \( r/z_0 \geq 5 \) is probably due to numerical confinement; as the particles are further
separated, larger computational boxes would be necessary to accurately isolate the interaction due
solely to the neighboring particle.

VIII. CONCLUSIONS

We presented here the theory of the hydrodynamic interactions of two spheres in a shear flow in
the presence of a plane rigid wall. This theory provides a reference for consistent direct numerical
or experimental studies of the particles’ trajectories. Some of the predictions of the theory have
been confirmed by direct numerical simulations in Poiseuille flow, demonstrating that neglecting
the farthest wall is a valid assumption and the theory holds at least down to distances from the wall
of five particle radii, \( z_0 \approx 5a \).

The immediate use of our work is the determination of the limitations of the BG theory [4]; see
also Ref. [2]. Our theory indicates that for interparticle distances \( r/a \) much smaller than \((z_0/a)^{3/5}\)
variations of the interparticle velocity with respect to the BG velocity is small. This condition,
ITZHAK FOUXON et al.

FIG. 13. Asymptotic vertical velocity of particle 2 relative to particle 1 as a function of the horizontal separation, at $z_0 = 5a$ (cf. Fig. 1). We focus on the range where the theory predicts change of sign of the velocity and the associated critical point. The theory is seen to hold accurate predictions even in geometrically confined Poiseuille flows.

$r \ll z_0^{3/5} a^{2/5}$, is stricter than the naive estimate $r \ll z_0$. If this condition is not met, then the wall correction to the BG interparticle velocity is not small. The trajectories are then significantly altered in comparison with the BG predictions, both quantitatively and qualitatively.

Generally speaking our approach to the problem relies on finding the image of the full BG flow that describes particles’ interactions in shear flow. It might be anticipated that the above critical distance $z_0^{3/5} a^{2/5}$ follows from the comparison of the scalings of the BG velocity with that of the image. In fact, the distance $\propto z_0^{1/5}$ arises by comparing the BG relative velocity $\propto 1/x^4$ with that $\propto x/z_0^5$ due to the image flow; see Sec. III. However, we did not find a simple explanation for $\propto 1/x^4$ and $\propto x/z_0^5$ scalings.

Corrects due to the wall can also be relevant at $r \ll z_0^{3/5} a^{2/5}$ despite their smallness. The reason is that the global behavior of the BG trajectories passing near the separatrix is sensitive to small perturbations. Thus, perturbations originating from the wall presence, Brownian noise, gravity, finite roughness of the particles’ surface or any other source, may easily change the global portrait of the interactions. All the closed trajectories of the classic BG solution [4] can be altered quite significantly by small perturbations, since they all pass near the separatrix. Indeed when particles, orbiting around each other in the symmetry plane, reach the vertical (side-by-side) orientation, the maximal distance between them is of order of $10^{-5}a$; see Ref. [5]. The wall, even a distant one, can produce a small upward displacement which would shrink the region of closed trajectories. This is in fact what we see in the simulations where the separatrix in the presence of the wall crosses the $z$ axis at shorter distance from $z - 2a$ than without the wall. However, our simulations are not built for resolving distances as small as $10^{-5}a$ so this initial observation demands further, more accurate studies, which can take advantage of the evolution equation for the interparticle separation derived here.

We notice that the problem considered here seemingly has a hidden symmetry. The presence of the wall makes the top-down symmetry, which is displayed by the trajectories, nonevident.
Moreover, it is not so evident why the separatrices form a surface of rotation in both the BG and our cases.

Strictly speaking our analysis is not complete. The leading order correction that we found has naive order of smallness $z_0^{-2}$, and not the actually holding $z_0^{-3}$. We found this from the detailed calculation that revealed the vanishing of the $z_0^{-2}$ contribution due to symmetry. It is possible that the symmetry would be irrelevant for the next order term which has the naive order of magnitude of $z_0^{-3}$ and it cannot be neglected. We consider this scenario implausible and make the conjecture that the next order term is actually $O(z_0^{-4})$ and can be consistently neglected. Proving this conjecture theoretically is a formidable task which was not undertaken here. It seemed more practical to test the predictions that we made by direct numerical simulations of the motion of two spheres in a shear flow in the presence of a wall. The performed numerical simulations of the Poiseuille flow closely confirmed the predictions of our theory.

Another confirmation of our theory comes from the previous, unguided by the theory, simulations of Ref. [7]. This work considered the shear flow between two parallel planes induced by the motion of the upper plane. This problem, with both walls included, could be considered as in Sec. II by using the Green’s function for the Stokes flow between two infinite planes [11], which however is beyond the scope of the present paper. The interacting spheres in Ref. [7], however, were located closer to the immobile lower wall which makes our theory applicable at least qualitatively. The phase portrait of Ref. [7] for the evolution of the interparticle distance in the symmetry plane agrees remarkably well with that provided here, though it lacks the neutral equilibrium point and the closed trajectories revolving around it. The authors observed the saddle point at $z_0 = 4.8$ with distance 10 between the walls. In this case, our theory applies only qualitatively. However, when we use our formula $(32z_0^3/15)^{1/5}$ for the position of the saddle point, we find that our prediction agrees very well with the numerical findings of Ref. [7]. All these provide strong evidence for validity of our theory.

The complete proof showing that our open trajectories with sign-reversal of the vertical separation describe swapping of the vertical positions requires the computation of the vertical coordinate of the center of mass after the interaction. Although as we argued above, this seems inevitable, a proof demands the study of the motion of the center of mass, which was not undertaken here (the formulas of Sec. II can be used for this aim). For an unbounded shear flow, the motion of the center of mass could be obtained using the shear resistance matrix, function of the instantaneous distance between the spheres. This matrix can be written in terms of scalar coefficient functions, similar to $A$ and $B$, with the asymptotic form of this matrix obtained at large separations in Ref. [14] (see also Ref. [5]). Considering this matrix and the solution for the interparticle distance as a function of time as given, one can readily find the center of mass velocity as a function of time. In our case the calculations are even more involved due to the presence of the wall. This is therefore left for future work.

The numerical and experimental tests of our predictions may focus on the emergence of the neutrally stable bound state, when the particle pair flows as a whole at some fixed distance from the wall $z_0$. The horizontal component of the interparticle distance in this state belongs to the circle of radius $4z_0$, although at small $z_0$ some deviations from $4z_0$ must occur.

The fluid inertia may have nontrivial effect on the relative motion of two spheres in shear flow. It was observed in Ref. [26] that the BG trajectories are altered by finite but yet small Reynolds number $Re = 0.1$. Besides the open and closed BG-type trajectories, the authors found reversing trajectories that are similar to the swapping trajectories of Ref. [7], considered here, and recirculating trajectories of Ref. [27]. The authors also observed spiralling trajectories, that do not have a counterpart at zero $Re$, and did not observe the dancing trajectories discovered here. The authors ascribed the observations to the effect of finite $Re$ of unbounded shear flow, despite being aware that reversing trajectories could be caused by the boundaries. At the same time they found that variation of the computational domain in the streamwise direction does alter the trajectories, so that the simulation results are influenced by the boundaries. The numerical simulations performed
here demonstrate that the effects of the boundaries become negligible for the flow domain which is twice longer in the streamwise direction than that used in Ref. [26]. Future work on the effect of the finite fluid inertia must carefully and fully separate the effects by independent variation of Re and $z_0$ in wide intervals. Notice that even though our numerical simulations used finite Re = 0.1, there is an excellent agreement with theoretical predictions corresponding to Re = 0, indicating that the described phenomena should be attributed to the wall-bounded flow and not the weak fluid inertia.

Since the experiments of Refs. [8–10] used droplets and not rigid particles, we shall briefly address how the results obtained for the rigid particles here would change for droplets. Close interactions of rigid particles and droplets are quite different, both qualitatively and quantitatively; see, e.g., Ref. [2]. However, at large separations, when the effects of the wall are most relevant, the differences seem to be less significant. We have confirmed this again using direct numerical simulations for two liquid droplets in the same setup as for the solid particles in Sec. VII. We verified that $V_z > 0$ at $r/z_0 = 3$ while $V_z \lesssim 0$ at $r/z_0 = 5$. Thus, there is a point within this range where the velocity vanishes, as in the case of rigid particles. Therefore at least the prediction of the stationary point holds also in the case of liquid droplets. This suggests that the existence of states of marginal equilibrium is a robust phenomenon for pair of particles flowing next to a wall.

The theory presented here has direct generalisations to other distant boundaries. The developed approach can also be used to study the hydrodynamic interactions between suspended particles in other confined shearing flows, such as, e.g., Couette flow. The case of a third particle at a finite distance from the pair of spheres in an unbounded shear flow is also of interest. When the driving flow is enclosed between two parallel planes (i.e., a slit geometry), as in Ref. [7], the inclusion of the second plane is required for a theoretical analysis, as suggested above.

The present finding of stable configurations of pairs of particles due to hydrodynamic interactions is probably due to the fact that the position of one of the three bodies in interaction—the wall—is fixed. The question whether such configurations can exist for three or more flowing particles is left for future work.

APPENDIX A: INTEGRAL REPRESENTATION OF SHEAR FLOW ROUND SPHERES

We derive here the integral representation of the flow round spheres driven by shear in an unbounded fluid. The flow obeys

$$\nabla p = \eta \nabla^2 u, \quad u(\infty) \sim \dot{\gamma} z \hat{x}, \quad \nabla \cdot u = 0, \quad u(S_\alpha) = V_\alpha + \Omega_\alpha \times (x - x_\alpha),$$

where $\dot{\gamma}$ is the shear rate and as in the main text $\alpha = 1, 2$ are the indices of the spheres and $x_\alpha$ are the coordinates of the centers. Translational and angular velocities are determined from the conditions that the fluid applies to each particle zero net force and torque,

$$\int \sigma_{ik} dS_\alpha k = 0, \quad \int (x - x_\alpha) \times \sigma_{ik} dS_\alpha k = 0, \quad \sigma_{ik} \equiv -p \delta_{ik} + \eta (\nabla_i u_k + \nabla_k u_i),$$

where $\sigma_{ik}$ is the stress tensor. We use the Lorentz-type identity for $x'$ outside the volume of the spheres,

$$u_i(x') \delta(x' - x) = \frac{\partial}{\partial x'_k} \left[ \frac{Y_{il}(x - x') \sigma_{ik}(x')}{8\pi \eta} + u_l(x') \Sigma_{ikl}(x - x') \right].$$
where \( Y_{il} \) is defined in Eq. (7) and \( \Sigma_{ilk} \) defines the stress tensor of the Stokeslet. We have (our definition differs from Ref. [2] by insignificant permutation of indices of the symmetric tensor \( \Sigma_{ilk} \)),

\[
Y_{il} = \frac{\delta_{il}}{r} + \frac{r_i r_l}{r^3}, \quad \Sigma_{ilk} = \frac{1}{8\pi} \left( \frac{\partial Y_{il}}{\partial r_k} + \frac{\partial Y_{ik}}{\partial r_l} \right) - \frac{r_i \delta_{lk}}{4\pi r^5} = -\frac{3}{4\pi} \frac{r_i r_l r_k}{r^5},
\]

\[
\frac{\partial}{\partial x_k} \Sigma_{ilk}(x - x') = \delta_{il} \delta(x - x').
\]

Integrating Eq. (A3) over \( x' \) outside the particles, we find

\[
u_i(x) = \int_{S_{\infty}} \left( \frac{Y_{il}(x - x') \sigma_{lk}(x')}{{8\pi \eta}} + \nu_l(x') \Sigma_{ilk}(x - x') \right) dS' = \sum_a \int_{S_a} \frac{Y_{il}(x - x') \sigma_{lk}(x') dS'}{{8\pi \eta}}, \tag{A5}
\]

where the direction of the normals is outward from the surfaces and \( S_{\infty} \) is the spherical surface with radius \( R \) taken to infinity. The prime designates that the integrals are over the \( x' \) variable and the term with an integral of \( \Sigma \) over the particle surfaces vanishes by the rigid body boundary condition [2,12,18]. We observe that the disturbance of the flow caused by the spheres vanishes at infinity so that

\[
u \sim \gamma \hat{z} + o(\text{const}), \quad \sigma_{lk} \sim \eta \gamma (\delta_{il} \delta_{lz} + \delta_{lx} \delta_{iz}) + o(r^{-1}).
\]

We use these asymptotic forms for obtaining the integrals over \( S_{\infty} \). Keeping the lowest order nonvanishing term in the Taylor series of \( Y_{il}(x - x') \) in \( x' \),

\[
\int_{S_{\infty}} Y_{il}(x - x') \sigma_{lk} dS' = \frac{-x_m}{8\pi \eta \gamma} \int_{S_{\infty}} \left( \delta_{lz} x' + \delta_{lx} \right) \sigma_{lk} dS' = \frac{-3}{8\pi \eta \gamma} \int_{S_{\infty}} \delta_{lz} x' dS' = \frac{-3}{8\pi \eta \gamma} \int_{S_{\infty}} \delta_{lz} x' dS', \tag{A6}
\]

We find using the form of \( Y_{il} \) in Eq. (A4),

\[
\frac{\partial Y_{il}}{\partial r_m} = \frac{r^2 (r_l \delta_{in} + r_i \delta_{ln} - r_m \delta_{il})}{r^5} - \frac{3 r_i r_l r_m}{r^5}, \tag{A7}
\]

and obtain,

\[
\int_{S_{\infty}} \frac{Y_{il}(x - x') \sigma_{lk} dS'}{{8\pi \eta \gamma}} = \frac{-3}{8\pi \eta \gamma} \int_{S_{\infty}} \delta_{lz} x' dS' = \frac{-3}{8\pi \eta \gamma} \int_{S_{\infty}} \delta_{lz} x' dS'. \tag{A8}
\]

where angular brackets stand for averages over the unit sphere,

\[
\langle x_i x_k \rangle = \int_{x=1} \frac{x_i x_k dS}{4\pi} = \frac{\delta_{ik}}{3}, \quad \langle x_i x_k x_l x_m \rangle = \frac{\delta_{il} \delta_{km} + \delta_{im} \delta_{lk}}{15}. \tag{A9}
\]

Further, by collecting the different terms,

\[
\int_{S_{\infty}} \frac{Y_{il}(x - x') \sigma_{lk} dS'}{{8\pi \eta \gamma}} = \frac{\delta_{li} x + \delta_{lk} z}{3}, \tag{A10}
\]

We consider similarly the remaining integral over \( S_{\infty} \),

\[
\int_{S_{\infty}} \nu_l(x') \Sigma_{ilk} (x - x') dS'_k = \gamma \int_{S_{\infty}} \psi' \Sigma_{ilk} (x - x') dS'_k = x_m \gamma \int_{S_{\infty}} \psi' \frac{\partial \Sigma_{ilk} (x')}{\partial x'_m} dS'_k. \tag{A11}
\]

We have from Eq. (A4) that

\[
\frac{\partial \Sigma_{ilk}}{\partial r_m} = \frac{3}{4\pi} \left( \frac{5 x_l x_k r_m}{r^7} - \frac{r_i r_l \delta_{mk} + r_i x_m \delta_{mk} + x_k \delta_{mk}}{r^5} \right).
\]
and

$$\int_{S_\infty} u_t(x') \Sigma_{lik}(x-x') dS_k' = 3x_m \dot{y} \left[ 4x \delta z - z \delta x - xz \delta m \right].$$

(A11)

We obtain using Eq. (A8),

$$\int_{S_\infty} u_t(x') \Sigma_{lik}(x-x') dS_k' = \dot{y} \left( \frac{4 \delta_{i4} y - \delta_{i3} x}{5} \right).$$

(A12)

Collecting the terms in Eq. (A5), we obtain the integral representation given by Eq. (7) in the main text. This representation leads to Eq. (17) in the main text when taking $x$ on the surface of one of the spheres and using the proper boundary condition. The representation could also be derived by considering the standard integral representation for the correction flow $u = \dot{y} z \hat{x}$, which also obeys the Stokes equation. In that approach one would need to evaluate integrals on the particles’ surfaces instead of $S_\infty$ to find Eq. (7).

The integral representation in Eq. (7) gives readily the multipole expansion of the flow at large distances $x \gg x'$, see Refs. [2,18]. The leading order term is provided in Eq. (8) of the main text where we use the condition of zero force. This approximation holds at $|x - x_o|$ much larger than the radii of the spheres.

**APPENDIX B: DYNAMICAL EQUATIONS IN CARTESIAN COORDINATES**

We can derive an explicit expression for $\delta V_i$ using Eqs. (9) and (25). To this end, we introduce $s^2 = x^2 + y^2 + 4z_0^2$, $\sigma = z^2 - 4z_0^2$ and $g^2 = x^4 + y^4 + 4z_2^2$. We find after simplifications that $\delta V_i$ can be written as sums over four components $c^k_i$ (we use dimensionless time $\dot{\gamma} t$).

$$\delta V_x = \frac{5z_0}{r^2} \sum_{k=1}^{4} c^k_x, \quad \delta V_y = \frac{5xy}{r^2} \sum_{k=1}^{4} c^k_y, \quad \delta V_z = \frac{5x}{r^2} \sum_{k=1}^{4} c^k_z.$$  

(B1)

The components of $\delta V_x$ are given by

$$c^1_x = \frac{y^2 [2s^2 x^2 - (s^2 - 5y^2) \sigma ] (r^2 L + 2x^2 M)}{2s^2}, \quad c^2_x = x^2 c^3_y, \quad c^3_y = \frac{2z_0}{\sigma^2} \left[ (1 + K) r^4 + (x^2 + z^2) r^2 L(r) + 2x^2 z^2 M \right],$$

$$c^4_y = -\frac{x^2 \sigma}{2s^2} \left[ r^2 (5y^2 - s^2) L + [s^2 (r^2 + 2x^2) - 5g^2] M \right],$$

(B2)

where the components of $\delta V_y$ read

$$c^1_y = \frac{[2s^2 y^2 - (s^2 - 5y^2) \sigma ] (r^2 L + 2x^2 M)}{2s^2}, \quad c^2_y = \frac{2z_0}{\sigma^2} (r^2 L + 2z^2 M),$$

$$c^3_y = \frac{(s^2 - 3y^2) r^2 L + (3g^2 - r^2 s^2) M}{3s^2},$$

$$c^4_y = -\frac{\sigma}{2s^2} \left[ r^2 (5y^2 - 3s^2) L + [s^2 (r^2 + 2y^2) - 5g^2] M \right].$$

(B3)

Finally, the components of $\delta V_z$ are

$$c^1_z = \frac{\sigma}{2s^2} \left( s^2 - 20z_0^2 \right) [r^4 (1 + K + L) + 2z^2 (r^2 - z^2) M], \quad c^2_z = \frac{2z_0^2 z_0}{\sigma^2} [r^2 L + (3z^2 - r^2) M],$$

$$c^3_z = z^2 c^3_y, \quad c^4_z = \frac{y^2 z_0^2}{s^2} (r^2 L + 2x^2 M).$$

(B4)
We observe from Eqs. (23) and (B1)–(B4) that $V_i = V_i^0 + \delta V_i$ obeys the symmetries,

$$
\begin{align*}
V_i(-x, y, z) &= V_i(x, y, z), & V_i(x, y, -z) &= -V_i(x, y, z), & V_i(x, -y, z) &= V_i(x, y, z), \\
V_j(-x, y, z) &= -V_j(x, y, z), & V_j(x, -y, z) &= -V_j(x, y, z), & V_j(x, y, -z) &= -V_j(x, y, z), \\
V_k(-x, y, z) &= -V_k(x, y, z), & V_k(x, -y, z) &= V_k(x, y, z), & V_k(x, y, -z) &= V_k(x, y, z).
\end{align*}
$$

(B5)

These symmetries, which are rather simple in the case of the infinitely separated wall [4], are not destroyed by the corrections due to the finiteness of the separation. They allow us to confine the study of the trajectories to the octant $x > 0$, $y > 0$ and $z > 0$.

---

[25] Here, we exploit the fact that the particles travel nearly at a constant velocity relative to the wall despite the relative influence. This allows us to subtract the velocity of particle 1, taken as the undisturbed velocity evaluated at its initial center location, from the underlying flow to obtain a moving reference frame. Doing so automatically satisfies the Galilean invariance and significantly reduces the computational cost by limiting the size of the simulation box.
